

Module 15) Advance Python Programming

1. Printing on Screen

- **Introduction to the print() function in Python**

The print() function in Python is one of the most commonly used functions, especially for beginners. It is used to **output information to the console** (also known as the standard output). Here's a basic introduction to how it works:

Syntax:

```
print(object(s), sep=' ', end='\n', file=sys.stdout, flush=False)
```

print() is used to display output.

It accepts multiple arguments and can be customized using sep and end.

It's essential for debugging and user interaction in console-based programs

- **Formatting outputs using f-strings and format().**

1. f-Strings (Formatted String Literals)

- Introduced in **Python 3.6**, f-strings provide a concise and readable way to include variables and expressions inside string literals.
- An f-string is created by prefixing a string with the letter f or F.
- Expressions inside curly braces {} are evaluated at runtime and inserted into the string.

- f-strings support complex expressions, formatting of numbers, alignment, and more.
- They are generally faster and more readable compared to older formatting methods.

Example Syntax:

```
f"Hello, {name}. You are {age} years old."
```

2. **format() Method**

- The `format()` method is a string method that allows insertion of values into placeholders defined by `{}`.
- It can use **positional** or **keyword arguments**, which are substituted into the placeholders.
- You can control formatting, such as decimal precision, padding, and alignment.
- It works in both Python 2.7 and Python 3.x.
